A-STABLE HIGH ORDER BLOCK IMPLICIT METHODS FOR PARABOLIC EQUATIONS

SHISHUN LI†, JING-YUAN WANG‡, AND XIAO-CHUAN CAI§

Abstract. In this paper, we consider the time integration of parabolic equations with block implicit methods (BIM). Depending on the size of the block, high order BIM with $A$-stability are designed without the need of multiple initial guesses. Similar to Runge-Kutta methods, a BIM can be defined by a tableau including two matrices and two vectors. In addition to the general methodology of BIM, we show a special scheme defined by a positive definite matrix and a positive diagonal matrix; both matrix properties are desirable but not available in Runge-Kutta methods. Moreover, we show that the traditional finite element theory for parabolic problems discretized by the backward Euler or Crank-Nicolson schemes can also be extended to BIM. Finally, we introduce some domain decomposition preconditioners for the linear systems of algebraic equations arising from the block implicit discretization in time and finite element in space. Some numerical results are also reported to show the effectiveness of BIM.

Key words. Block implicit method, $A$-stability, domain decomposition preconditioner, finite element, parabolic problems.

1. Introduction. Many time-stepping methods are available for the time integration of parabolic equations [9, 23, 24, 48]. There are two families of classical methods: one-step (multistage) methods and linear multistep (one stage) methods (LMM). Runge-Kutta and Adams methods are examples that are widely used. The methods can be used in their explicit form if the problem is non-stiff or in the implicit form if the problem is stiff. LMM is relatively easy to implement but limited to the Dahlquist order stability barrier [18] and start-up issues [14, 22]. On the other hand, implicit Runge-Kutta methods (IRK) possess favorable stability properties, offer high order of accuracy, and no start-up issues. Among the varieties of IRK, diagonally IRK (DIRK) is preferred by most researchers and is widely used in practice due to its relative ease of implementation [32]. However, DIRK may suffer from the reduction of the order of accuracy and the stage-order is limited to two [24]. The fully IRK (FIRK) methods improve the stage-order, but a higher computational cost is required. Other high order methods with good stability properties have also been studied extensively, such as the general linear methods [9], Taylor Series (multi-derivative) methods [21], boundary value methods [8], exponential time-differencing methods [12, 13, 19, 26]. One particular class of methods that deserves further study and has the potential for many important applications is the so-called block implicit methods (BIM), which was developed by coupling multiple classical LMM schemes in a single method [7, 44, 45, 51, 52]. BIM overcomes the Dahlquist stability barriers and the start-up issues of LMM.

The idea of BIM was first proposed in [41], where the methods were used to provide starting values for predictor-corrector schemes. A BIM with block size $k$ can be described by a tableau

$$
\begin{pmatrix}
A & B \\
A^T & B^T
\end{pmatrix},
$$

where $A, B \in \mathbb{R}^{k \times k}$ and $a, b \in \mathbb{R}^k$ can be derived from the coefficients of LMM, and in this paper we refer to them as the BIM matrices and BIM vectors. BIM circumvents the order and stability barrier of LMM, and share some of the nice features of IRK [2, 5–7, 42]. However, BIM is not widely used because it requires the solving of a large and ill-conditioned algebraic system of equations at each iteration. For example, the discretization of a linear parabolic equation by BIM in time and the finite element in space produces a system of equations of the form

\[(1.1)\quad A \otimes M + \tau B \otimes K,\]

where $\otimes$ denotes the Kronecker tensor product, $\tau$ is the time step size, $M, K \in \mathbb{R}^{N \times N}$ denote the mass and the stiffness matrix, respectively. $N$ is the number of unknowns in space. (1.1) is larger and more difficult to deal with than the coefficients matrices resulting from, for example, the implicit Euler, Crank-Nicolson and LMM that are of the form $\alpha M + \beta \tau K$, where $\alpha > 0$ and $\beta > 0$ are constants.

One of the goals of this paper is to continue the study of BIM initiated in [51, 52]. We find the explicit relation between the BIM matrices $A$ and $B$ by employing the order conditions of LMM. This is important for the theoretical analysis of BIM and helpful for the construction of new algorithms with desirable properties. By employing the techniques in [3, 4, 27], we construct a special type of BIM algorithms such that the matrix $B^{-1}A$ is diagonally stable. In these algorithms, $B$ is a positive diagonal matrix and $A$ is a positive definite matrix. As a result, the matrix (1.1) has the same positive definiteness as the matrix $\alpha M + \beta \tau K$, and the corresponding linear systems are easier to precondition and solve. On the other hand, the FIRK matrices are dense and positive stable; i.e., the real part of the eigenvalues are positive [31, 34, 39], which makes the positive definiteness of the matrix $K$ in (1.1) useless.

In this paper, following the idea of [10, 11, 15, 36–38], we also introduce some parallel DD preconditioners for parabolic partial differential equations (PDEs) discretized by BIM in time and finite element in space. Similar to the implicit Euler and Crank-Nicolson methods for parabolic PDEs [48], the uniqueness of the solution can be proved by the Lax-Milgram theorem, and the a priori error estimates for finite element methods can also be established. Note that such analysis can not be obtained for FIRK since the FIRK matrices are only positive stable but not positive definite [40].

The rest of the paper is organized as follows. In Section 2, we present some motivating examples. In Section 3, we first study BIM with $A$-stability and present the matrix $B^{-1}A$ explicitly, then we construct BIM by selecting special $A$ and $B$. In Section 4, a comparison with FIRK is presented to show that BIM is more competitive. Some DD preconditioners in the tensor form are introduced in Section 5 for linear parabolic PDEs discretized with BIM in time and finite element in space. Finally, some conclusions are given in Section 6.

2. Block implicit methods: Formulation, order of convergence and stability.
In this section, we first review briefly the one-step and multistep algorithms. Then present some motivating examples to show why BIM is important. In particular we show how to combine a few “not-so-good” methods (in terms of order, and/or stability, and/or the requirement of multiple initial values) into a single block method with all the desirable properties. After these interesting examples, we derive the general form of BIM and introduce several types of stabilities.
2.1. A brief review of time-stepping methods. We consider a one-dimensional initial value problem

\[
\begin{align*}
\begin{cases}
y'(t) = f(t, y), & t \in (0, T], \\
y(t_0) = y_0
\end{cases}
\end{align*}
\]

(2.1)

discretized on a uniform temporal mesh \(0 = t_0 < t_1 < \cdots < t_N = T\) with the time step size \(\tau = t_n - t_{n-1}\). We denote by \(y_n\) as the solution at time \(t_n\). A one-step method for solving (2.1) can be described as

\[
y_{n+1} = R(z)y_n, \quad n = 0, 1, \ldots, N - 1,
\]

(2.2)

where \(R(z) = P(z)/Q(z)\) is a rational function, \(P(z)\) and \(Q(z)\) are polynomials of degree \(m\) and \(j\), respectively. The function \(R(z)\) is called the stability function of the method [24], and it can be interpreted as the numerical solution after one step of the Dahlquist test equation

\[
y' = \lambda y, \quad y_0 = 1, \quad z = \tau \lambda.
\]

(2.3)

The set \(S = \{z \in \mathbb{C} : |R(z)| \leq 1\}\) is called the stability domain of the method.

**Definition 2.1.** (Dahlquist 1963 [18]) A method, whose stability domain satisfies

\[
S \supset \mathbb{C}^- = \{z : \text{Re } z < 0\},
\]

is called \(A\)-stable, where \(\mathbb{C}^-\) denotes the entire left half-plane.

Suppose \(R(z)\) is an arbitrary rational approximation of order \(p\) with \(m\) zeros and \(j\) poles. The following theorems for the \(A\)-stability of \(R(z)\) can be found in [24].

**Theorem 2.2.** (Crouzeix & Ruamps 1977 [17]) Suppose \(p \geq 2j - 2\), \(|R(\infty)| \leq 1\), and the coefficients of the denominator \(Q(z)\) have alternating signs. Then, \(R(z)\) is \(A\)-stable.

**Theorem 2.3.** Suppose \(p \geq 2j - 3\), \(R(z)\) is \(I\)-stable, and the coefficients of \(Q(z)\) have alternating signs. Then, \(R(z)\) is \(A\)-stable.

A \(k\)-step LMM is often written as

\[
\alpha_k y_{n+k} + \cdots + \alpha_1 y_{n+1} + \alpha_0 y_n = \tau(\beta_k f_{n+k} + \cdots + \beta_1 f_{n+1} + \beta_0 f_n),
\]

(2.4)

where \(\alpha_k = 1\), \(|\alpha_0| + |\beta_0| > 0\). If (2.4) is of order \(p\), the coefficients \(\alpha_j\) and \(\beta_j\) \((j = 0, 1, \cdots, k)\) satisfy

\[
\begin{align*}
c_0 &= \sum_{j=0}^{k} \alpha_j = 0, \\
c_1 &= \sum_{j=0}^{k} j \alpha_j - \sum_{j=0}^{k} \beta_j = 0, \\
c_2 &= \frac{1}{2} \sum_{j=0}^{k} j^2 \alpha_j - \sum_{j=0}^{k} j \beta_j = 0, \\
&\vdots \\
c_p &= \frac{1}{p!} \sum_{j=0}^{k} j^p \alpha_j - \frac{1}{(p-1)!} \sum_{j=0}^{k} j^{p-1} \beta_j = 0, \quad p = 3, 4, \cdots.
\end{align*}
\]

(2.5)

(2.5) is called the order conditions. Although LMM is relatively easy to implement, it is limited by the Dahlquist order stability barrier [18].
2.2. Some motivating examples. We consider two simple equations.

**Example 1.** \( y' = -3y, \quad y(0) = 1, \quad t \in (0, 2]. \)

**Example 2.** \( y' = -2000(y - \cos(t)), \quad y(0) = 0, \quad t \in (0, 1.5]. \)

Below we mention three methods to serve as the basis of the discussion.

**Method A** (second-order):

\[
y_{n+2} - y_n = 2\tau f_{n+1}, \quad \text{with given } y_0 \text{ and } y_1,
\]

which is a two-step method often referred to as the mid-point rule.

**Method B** (third-order):

\[
y_{n+2} + 4y_{n+1} - 5y_n = \tau (4f_{n+1} + 2f_n), \quad \text{with given } y_0 \text{ and } y_1,
\]

which is a two-step explicit method.

**Method C** (third-order):

\[
y_{n+2} - 3y_{n+1} + 2y_n = \frac{\tau}{12} (7f_{n+2} - 8f_{n+1} - 11f_n), \quad \text{with given } y_0 \text{ and } y_1,
\]

which is a two-step implicit method.

Methods A, B and C are two-step linear methods and they are known to be not stable, and in Figure 1, the instability can be seen clearly from the numerical solutions obtained with several different mesh sizes and a comparison with the known exact solution of Example 1. Because of the instability, these methods are never used in practice. Next, we come up with some block implicit methods designed by combining some stable and unstable methods into a system of methods. Methods D, E and F shown below are designed by coupling two or three classical linear multistep methods (stable or unstable), but only one given initial value \( y_0 \). Since they are block methods, the solutions at two or three time steps are obtained simultaneously. It is interesting to note that these three methods are all stable from Figure 2. Moreover, Table 1 shows that Methods D, E and F are second-order, fourth-order and third-order, respectively.

![Fig. 1: Numerical solutions of Example 1 computed by the Methods A (left), B (middle) and C (right)](image)

**Method D** (second-order):

\[
\begin{align*}
    y_{n+2} - y_n &= 2\tau f_{n+1}, \\
    3y_{n+2} - 4y_{n+1} + y_n &= 2\tau f_{n+2},
\end{align*}
\]

</table>

which is an one-step implicit method (with initial value $y_0 = y(0)$) obtained by coupling (2.6) and the BDF2 rule.

Method E (fourth-order):

$$
\begin{align*}
    y_{n+2} + 4y_{n+1} - 5y_n &= \tau(4f_{n+1} + 2f_n), \\
    y_{n+2} - 3y_{n+1} + 2y_n &= \frac{\tau}{12}(7f_{n+2} - 8f_{n+1} - 11f_n),
\end{align*}
$$

which is an one-step implicit method (with initial value $y_0 = y(0)$) obtained by coupling (2.7) and (2.8).

Method F (third-order):

$$
\begin{align*}
    12y_{n+3} - 12y_{n+2} &= \tau(23f_{n+2} - 16f_{n+1} + 5f_n), \\
    11y_{n+3} - 18y_{n+2} + 9y_{n+1} - 2y_n &= 6\tau f_{n+3}, \\
    3y_{n+3} - 3y_{n+1} &= \tau(-2f_{n+3} + 13f_{n+2} - 8f_{n+1} + 3f_n),
\end{align*}
$$

which is an one-step implicit method (with initial value $y_0 = y(0)$) obtained by coupling three linear 3-step methods.

It is clear that the new block methods D, E and F all have better stability than the classical linear multistep method. The solutions at $k$ time steps may behave differently since the corresponding stability functions have different properties. Below we introduce some terminologies to describe these stabilities:

DEFINITION 2.4. Assume that $y_{n+1}, y_{n+2}, \ldots, y_{n+k}$ are computed simultaneously by employing the initial value $y_n$. Then, the method is

(1) strong $k$-step stable if $|y_{n+k}| \leq |y_{n+k-1}| \leq \cdots \leq |y_{n+1}| \leq |y_n|$.
(2) \( k \)-step stable if \(|y_{n+i}| \leq |y_n|\) for all \(1 \leq i \leq k\);
(3) \( k^{th}\)-step stable if \(|y_{n+k}| \leq |y_n|\).

Note that this definition is exactly the same as that for the classical one-step or multistep methods when \(k = 1\).

2.3. Derivation of block implicit methods. In this section, we derive a family of block implicit methods based on the classical linear multistep methods.

**Definition 2.5.** (Block implicit method with block size \(k\)) For a given initial value \(y_n\), the problem (2.1) is solved by the following \(k\) by \(k\) system of algebraic equations

\[
\begin{align*}
(2.12.1) \quad a_{1k}y_{n+k} + \cdots + a_{11}y_{n+1} + a_{10}y_n &= \tau(b_{1k}f_{n+k} + \cdots + b_{11}f_{n+1} + b_{10}f_n), \\
(2.12.2) \quad a_{2k}y_{n+k} + \cdots + a_{21}y_{n+1} + a_{20}y_n &= \tau(b_{2k}f_{n+k} + \cdots + b_{21}f_{n+1} + b_{20}f_n), \\
& \vdots \\
(2.12.k) \quad a_{kk}y_{n+k} + \cdots + a_{k1}y_{n+1} + a_{k0}y_n &= \tau(b_{kk}f_{n+k} + \cdots + b_{k1}f_{n+1} + b_{k0}f_n),
\end{align*}
\]

where \(|a_{i0}| + |b_{i0}| > 0\) and each formula (2.12.\(i\)) \((1 \leq i \leq k)\) satisfies the order conditions (2.5). The error is \(C_{p+1} = (c_{1,p+1} c_{2,p+1} \cdots c_{k,p+1})^T\) and \(c_{i,p+1}\) is the error constant of the formula (2.12.\(i\)) \((1 \leq i \leq k)\).

It is convenient to represent a BIM by a partitioned tableau of the form

\[
\begin{pmatrix} A & B \\ a^T & b^T \end{pmatrix},
\]

where \(a = (a_{10} a_{20} \cdots a_{k0})^T\), \(b = (b_{10} b_{20} \cdots b_{k0})^T\), and the BIM matrices

\[
A = \begin{pmatrix} a_{11} & a_{12} & \cdots & a_{1k} \\
 a_{21} & a_{22} & \cdots & a_{2k} \\
 \vdots & \vdots & \ddots & \vdots \\
 a_{k1} & a_{k2} & \cdots & a_{kk} \end{pmatrix} \quad \text{and} \quad B = \begin{pmatrix} b_{11} & b_{12} & \cdots & b_{1k} \\
 b_{21} & b_{22} & \cdots & b_{2k} \\
 \vdots & \vdots & \ddots & \vdots \\
 b_{k1} & b_{k2} & \cdots & b_{kk} \end{pmatrix}.
\]

Applying the above BIM to

\[y' = 0,\]

we have

(2.13) \[Ay = -ay_n,\]

where \(y = (y_{n+1} y_{n+2} \cdots y_{n+k})^T\). Since \(a_{i1} + \cdots + a_{i1} + a_{i0} = 0\) (consistency condition of LMM), it follows from Cramer’s rule that

\[y_{n+i} = \frac{|A_i|}{|A|}y_n = y_n, \quad (1 \leq i \leq k),\]

where \(A_i\) is the matrix \(A\) with the \(i^{th}\) column \(a_i\) replaced by the vector \(-a_i\). Therefore, the method is stable if \(A\) is nonsingular. Now, we introduce the definition for the stability of BIM.

**Definition 2.6.** (Block zero-stability) The BIM (2.12) is called \(k\)-step stable, if the BIM matrix \(A\) is nonsingular.
Applying the above BIM to Dahlquist test equation (2.3), we have

\begin{equation}
C(z)y \equiv (A - zB)y = (zb - a)y_n,
\end{equation}

where $z = \lambda \tau$.

Define the rational functions

\begin{equation}
R_{n+i}(z) = \frac{P_{n+i}(z)}{Q_{n+i}(z)}, \quad 1 \leq i \leq k.
\end{equation}

Here $P_{n+i}(z) = |C_i(z)| = |A_i - zB_i|$ and $Q_{n+i}(z) = |C_{i-1}(z)|$ or $Q_{n+i}(z) = |C(z)|$, where $C_0(z) = C(z)$ and $B_i$ ($1 \leq i \leq k$) is the matrix obtained by replacing column $i$ of $B$ by $-b$. Note that if (2.12) is block $k$-step stable, i.e., $A$ is nonsingular, the polynomial $|C_i(z)|$ is nonzero since the constant term is $|A|$. From (2.14), we have $y_{n+i} = \frac{|C_i(z)|}{|C(z)|}y_n$ and $y_{n+i} = \frac{|C_{i-1}(z)|}{|C(z)|}y_{n+i-1}$.

**Definition 2.7.** The sets

$$S_i = \{z \in \mathbb{C} : |R_{n+i}(z)| \leq 1\}, \quad 1 \leq i \leq k$$

are called the stability domains of the BIM.

i) If $S_i \supset \mathbb{C}^-$ for all $1 \leq i \leq k$, i.e., each $R_{n+i}(z) = |C_i(z)|/|C_{i-1}(z)|$ is $A$-stable, this method is called strong block $k$-step $A$-stable;

ii) If $S_i \supset \mathbb{C}^-$ for all $1 \leq i \leq k$, i.e., each $R_{n+i}(z) = |C_i(z)|/|C(z)|$ is $A$-stable, this method is called block $k$-step $A$-stable;

iii) If $S_k \supset \mathbb{C}^-$, i.e., $R_{n+k}(z) = |C_k(z)|/|C(z)|$ is $A$-stable, this method is called block $k^{th}$-step $A$-stable.

3. **Block implicit methods with $A$-stability.** BIM with $A$-stability was first studied based on the interpolatory formulas of Newton-Cotes type [51]. The coefficients of $|C(z)|$ and $|C_i(z)|$ can be obtained explicitly by using Newton-Cotes formulas. By using Routh scheme [16], it is proved numerically that the block size of $A$-stable BIM has to be less than or equal to 8. In this section, we further study BIM with $A$-stability by different techniques. Based on the Lyapunov stability theorem, we explicitly construct a type of BIM by choosing the BIM matrices $A$ and $B$.

3.1. **$A$-stability of BIM.** We first show that the equation (2.14) has a unique solution by employing the order conditions (2.5); i.e., the solution is uniquely determined by $B^{-1}A$, and is independent of the individual BIM matrices $A$ and $B$. Then, we present several BIM for some $k$ and prove their stability. Let

$$W = \begin{pmatrix} 1 & 1 & 1 & \cdots & 1 \\ 0 & 1 & 2 & \cdots & k \\ 0 & 1 & 2^2 & \cdots & k^2 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 1 & 2^k & \cdots & k^k \end{pmatrix} \quad \text{and} \quad H = \begin{pmatrix} 0 \\ 1 \\ \vdots \\ \vdots \\ k \end{pmatrix}$$

we have the following important lemma in [1].

**Lemma 3.1.** The elements of the matrix $W^{-1}HW$ are

$$(W^{-1}HW)_{ij} = \begin{cases} \sum_{p=1}^{i} \frac{1}{p} - \sum_{p=1}^{k-i} \frac{1}{p}, & i = j, \\ \frac{(-1)^{j-i}}{j-i} C_i^k C_j^k, & i \neq j, \quad i,j = 0,1,\ldots,k. \end{cases}$$
Here $C^k_i = \binom{k}{i}$ denotes the binomial coefficient.

Let $e_i$ be the column $i$ of the identity matrix $I \in \mathbb{R}^{k \times k}$, $e = (1, 1, \ldots, 1)^T \in \mathbb{R}^k$, $e_0 = (0, 0, \ldots, 0)^T \in \mathbb{R}^k$, $\bar{x} = (1, 2, \ldots, k)^T \in \mathbb{R}^k$ and $v = (1, 2, \ldots, k+1)^T$. Define $\bar{b} \in \mathbb{R}^k$ and $N \in \mathbb{R}^{k \times k}$ by

$$(-\bar{b})_i = \frac{(-1)^i}{C^k_i} \quad \text{and} \quad N_{ij} = \begin{cases} \sum_{p=1}^{i} \frac{1}{p} - \sum_{p=1}^{i-1} \frac{1}{p} + \frac{1}{i}, & i = j, \\ \frac{(-1)^{i-j}}{i-j} \frac{C^k_i}{j}, & i \neq j. \end{cases}$$

By replacing $e_i$ $(i = 1, 2, \ldots, k)$ in the identity matrix $I$ by $e$ and $-\bar{b}$, define the matrices $Q_i, I_i \in \mathbb{R}^{k \times k}$ as follows:

$$Q_i = [e_1 \cdots e_{i-1} e e_{i+1} \cdots e_k], \quad I_i = [e_1 \cdots e_{i-1} \bar{b} e_{i+1} \cdots e_k].$$

We obtain the following theorem.

**Theorem 3.2.** For BIM, the solution of (2.14) is unique, and the stability function is

$$R_{n+i}(z) = \frac{|C_i(z)|}{|C(z)|} = \frac{|NQ_i - zI_i|}{|N - zI|}.$$ \[\text{The error} \quad C_{p+1} = (D_0v - (p+1)N^{-1}v)/(k+2)!, \quad \text{where} \quad D_0 = \text{diag}(1, 2, \ldots, k).\]

**Proof.** Combining the order conditions (2.5) and (2.14), setting $c_2 = c_3 = \cdots = c_{k+1} = 0$, we have

$$AD_0C_1 = BC_1D_1,$$

where

$$D_0 = \begin{pmatrix} 1 \\ 2 \\ \vdots \\ k \end{pmatrix}, \quad D_1 = \begin{pmatrix} 2 \\ \vdots \\ k+1 \end{pmatrix}, \quad C_1 = \begin{pmatrix} 1 & 1 & \cdots & 1 \\ 2 & 2^2 & \cdots & 2^k \\ \vdots & \vdots & \ddots & \vdots \\ k & k^2 & \cdots & k^k \end{pmatrix}.$$ \[\text{Clearly,} \quad D_0, \quad D_1 \quad \text{and} \quad C_1 \quad \text{are nonsingular}. \] Then, we have

$$B = AN^{-1}, \quad N = C_1D_1C_1^{-1}D_0^{-1}.$$ \[\text{Therefore,} \quad C(z) = (A - zB) = AN^{-1}(N - zI).\]

Setting $c_1 = 0$ in (2.5), we have

$$\begin{pmatrix} a_{11} + 2a_{12} + \cdots + ka_{1k} = b_{10} + b_{11} + \cdots + b_{1k}, \\ a_{21} + 2a_{22} + \cdots + ka_{2k} = b_{20} + b_{21} + \cdots + b_{2k}, \\ \vdots \\ a_{k1} + 2a_{k2} + \cdots + ka_{kk} = b_{k0} + b_{k1} + \cdots + b_{kk} \end{pmatrix}.$$
Define $\vec{x} = (1, 2, \cdots, k)^T$, (3.6) implies
\[
A\vec{x} = b + Be.
\]
Hence,
\[
b = A\vec{x} - Be = AN^{-1}(N\vec{x} - e).
\]
Set $\bar{b} = N\vec{x} - e$, it follows from (3.4) and (3.7) that
\[
\bar{b} = C_1D_1^{-1}C_1D_0^{-1}\vec{x} - e = C_1D_1^{-1}C_1e - e = C_1D_0^{-1}C_1e.
\]
Setting $c_0 = 0$ in (2.5), we have
\[
a = -Ae.
\]
Therefore, combining (3.7), (3.8) and (3.9) we have
\[
C_{i}(z) = A_{i} - zB_{i}
\]
\[
= [a_1 \cdots a_{i-1} - a a_{i+1} \cdots a_k] - z[b_1 \cdots b_{i-1} - b b_{i+1} \cdots b_k]
\]
\[
= A[e_1 \cdots e_{i-1} e e_{i+1} \cdots e_k] - zB[e_1 \cdots e_{i-1} - \bar{b} e_{i+1} \cdots e_k]
\]
\[
(3.10) = AN^{-1}(NQ_i - zI_i).
\]
It follows from (3.5) and (3.10) that
\[
R_{n+i}(z) = \frac{|C_{i}(z)|}{|C(z)|} = \frac{|NQ_i - zI_i|}{|N - zI|}.
\]
Set
\[
F = \begin{pmatrix}
0 & 1 & \cdots & \\
& & \ddots & \\
& & & 1 \\
& \cdots & & \\
& & & 0
\end{pmatrix}_{(k+1)\times(k+1)}
\]
It is clear that
\[
(3.11) W^{T}F = \begin{pmatrix}
0 & e_{0}^{T} \\
e_{0} & D_{0}^{-1}C_{1}
\end{pmatrix}
\]
and
\[
H^{T} = F \begin{pmatrix}
0 & e_{0}^{T} \\
e_{0} & D_{0}
\end{pmatrix}.
\]
Therefore,
\[
W^{T}H^{T}W^{-T} = W^{T}F \begin{pmatrix}
0 & e_{0}^{T} \\
e_{0} & D_{0}
\end{pmatrix}W^{-T} = \begin{pmatrix}
1 & e_{0}^{T} \\
e & C_{1}
\end{pmatrix}F \begin{pmatrix}
0 & e_{0}^{T} \\
e_{0} & D_{0}
\end{pmatrix}W^{-T}
\]
\[
= \begin{pmatrix}
0 & e_{0}^{T} \\
e_{0} & D_{0}^{-1}C_{1}
\end{pmatrix} \begin{pmatrix}
0 & e_{0}^{T} \\
e_{0} & D_{0}
\end{pmatrix} \begin{pmatrix}
1 & e_{0}^{T} \\
-C_{1}^{-1} & C_{1}^{-1}
\end{pmatrix}
\]
\[
(3.12) = \begin{pmatrix}
-e_{0}^{T}D_{0}C_{1}^{-1}e & e_{0}^{T}D_{0}C_{1}^{-1} \\
-D_{0}^{-1}C_{1}D_{0}C_{1}^{-1}e & D_{0}^{-1}C_{1}D_{0}C_{1}^{-1}
\end{pmatrix}.
\]
Combining Lemma 3.1 and (3.12) we have
(3.13)
\[
(-D_0^{-1}C_1D_0C_1^{-1}e)_i = \frac{(-1)^i}{i!C_i^k} \quad \text{and} \quad (D_0^{-1}C_1D_0C_1^{-1})_{ij} = \begin{cases} 
\sum_{p=1}^{i} \frac{1}{p} - \sum_{p=1}^{k-i} \frac{1}{p} & i = j, \\
\frac{(-1)^{i-j} C_j^k}{i-j} & i \neq j.
\end{cases}
\]

Since \( N = D_0(D_0^{-1}C_1D_0C_1^{-1})D_0^{-1} + D_0^{-1} \), it follows from (3.4), (3.8) and (3.13) that
\[
(-\tilde{b})_i = \frac{(-1)^i}{i!C_i^k} \quad \text{and} \quad N_{ij} = \begin{cases} 
\sum_{p=1}^{i} \frac{1}{p} - \sum_{p=1}^{k-i} \frac{1}{p} + \frac{1}{i!} & i = j, \\
\frac{(-1)^{i-j} i C_j^k}{i-j} & i \neq j.
\end{cases}
\]

Let \( v = (1, 2^{k+1}, \ldots, k^{k+1})^T \), it follows from (2.5) and (3.4) that
\[
C_{p+1} = \frac{1}{(k+2)!}(AD_0v - (p+1)Bv).
\]

By the definition of error in (2.12), letting \( A = I \), we have \( B = N^{-1} \) and
\[
C_{p+1} = \frac{1}{(k+2)!}(D_0v - (p+1)N^{-1}v).
\]

This completes the proof.

From Theorem 3.2, we observe that the stability function \( R_{n+1}(z) = |C_i(z)|/|C(z)| \) is unique, so the stability of BIM is independent of the individual BIM matrices \( A \) and \( B \). Next, we present the stability functions for the cases \( k = 2, 3, \ldots, 8 \) and discuss their stability properties in detail. For convenience of the reader, we list the coefficients of the stability functions in Table 10 in Appendix A. Without affecting the stability function, the coefficients of \( |C_i(z)| \) and \( |C(z)| \) are multiplied by a common factor such that both of them are integers.

**Theorem 3.3.** BIM has the following stability properties.

(1) The methods are block \( k \)-step \( A \)-stable when \( k = 2 \) and \( k = 3 \).

(2) The methods are block \( k^{th} \)-step \( A \)-stable when \( 4 \leq k \leq 8 \).

**Proof.** (1) It is clear that \( k + 1 \geq 2k - 2 \) when \( k = 2 \) and \( k = 3 \), and
\[
\lim_{z \to \infty} R_{n+1}(z) = \lim_{z \to \infty} \frac{|C_i(z)|}{|C(z)|} \leq 1.
\]
Moreover, the signs of the denominator \( C(z) \) are alternating. From Theorem 2.2, we see that the methods are block \( k \)-step \( A \)-stable.

(2) If \( k = 4 \), since \( C(z) = C_4(-z) \), we have
(3.14) \[
E_{n+4}(y) = |C(iy)|^2 - |C_4(iy)|^2 = C(iy)C(-iy) - C_4(iy)C_4(-iy) = 0 \quad \forall y \in \mathbb{R}.
\]
So \( R_{n+4}(z) \) is \( I \)-stable. It is clear that \( k + 1 \geq 2k - 3 \) and the signs of the denominator \( C(z) \) are alternating. From Theorem 2.3, we see that the methods are block \( k \)-th step \( A \)-stable. Let \( E_{n+4}(y) = |C(iy)|^2 - |C_4(iy)|^2 \) \((i = 1, 2, 3)\), a straightforward
computation shows that $E_{n+i}(y) \geq 0$ does not hold for some $y \in \mathbb{R}$. Therefore, $R_{n+i}(z)$ ($i = 1, 2, 3$) is not $I$-stable and the methods are not block $k$-step $A$-stable.

When $k = 5, 6, 7, 8$, it is easy to show that $R_{n+k}(z)$ is $I$-stable, but the above techniques are not valid. Let $z = \alpha + i\beta$, if $k = 5$, we have

$$
|C(z)|^2 - |C_k(z)|^2
= -65760\alpha\beta^6 + 120(-2192\alpha^3 - 45\alpha)\beta^6 + 360(-1096\alpha^5 - 2765\alpha^3 - 630\alpha)\beta^4
+ 120(-2192\alpha^7 - 16455\alpha^5 - 22260\alpha^3 - 6300\alpha)\beta^2
- 65760\alpha^9 - 984600\alpha^7 - 3826800\alpha^5 - 4644000\alpha^3 - 1296000\alpha.
$$

It is clear that

$$
|C(z)|^2 \geq |C_k(z)|^2
$$

holds for all $\alpha \leq 0$. From Definition 2.1, we observe that $R_{n+k}(z)$ is $A$-stable.

If $k = 6$, we obtain

$$
|C(z)|^2 - |C_k(z)|^2
= -17640\alpha\beta^6 + (-88200\alpha^3 + 25872\alpha)\beta^6 + (-176400\alpha^5 - 249312\alpha^3 - 281400\alpha)\beta^6
+ (-176400\alpha^7 - 903168\alpha^5 - 630420\alpha^3 - 1205400\alpha)\beta^4
+ (-88200\alpha^9 - 954912\alpha^7 - 2386020\alpha^5 - 1863960\alpha^3 - 3528000\alpha)\beta^2
\tag{3.15}
$$

To show (3.15) is non-negative for all $\alpha \leq 0$, we first consider it’s first three terms (factoring out $\beta^6$) denoted as $f(\beta) = -176400\alpha\beta^4 + (-88200\alpha^3 + 25872\alpha)\beta^2 - 176400\alpha^5 - 249312\alpha^3 - 281400\alpha$, we compute the discriminant of the roots of the quadratic equation (in $\beta^2$),

$$
\Delta = (-88200\alpha^3 + 25872\alpha)^2 - 3 \times 17640\alpha \times (176400\alpha^5 + 249312\alpha^3 + 281400\alpha)
= -4667544000\alpha^3 - 22155275520\alpha^4 - 1316198016\alpha^2
\tag{3.16}
$$

which implies $f(\beta) \geq 0$ for all $\alpha \leq 0$. Next consider the rest of the terms in (3.15) as a polynomial in $\alpha$, we see that all coefficients are non-negative if $\alpha \leq 0$. Then, $|C(z)|^2 \geq |C_k(z)|^2$ holds for all $\alpha \leq 0$, and this shows that the method is block $k$th-step $A$-stable.

When $k = 7$ and $k = 8$, it is easy to see that $E_{n+k}(y) = |C(iy)|^2 - |C_k(iy)|^2 = 0$ holds for all $y \in \mathbb{R}$ since $|C(z)| = |C_k(-z)|$, thus $R_{n+k}(z)$ is $I$-stable. Unfortunately,
we are unable to prove that $R_{n+k}(z)$ is analytic by the above techniques. The roots of the function $|C(z)|$ are computed numerically and shown in Table 2. It is clear that the real parts of all the roots are positive, therefore $R_{n+k}(z)$ is analytic and this method is block $k^{th}$-step A-stable.

Theorem 3.3 shows that BIM is $k^{th}$-step A-stable when $4 \leq k \leq 8$, i.e., the functions $R_{n+i}(z)$ ($1 \leq i < k$) are not A-stable. So it is interesting to study the stability of $R_{n+i}(z)$ ($1 \leq i < k$), as an example, for the special case of $k = 8$, we present the stability regions in Figure 3. It is clear that the stability region of $R_{n+8}(z)$ coincides exactly with the entire negative half-plane $\mathbb{C}^-$, implying that this method is block $k^{th}$-step A-stable. Moreover, the subfigures (a) to (g) show that $R_{n+i}(z)$ ($1 \leq i \leq 7$) is “nearly” A-stable. They are called $A(\alpha)$-stable in [53].

![Stability Regions](Fig3.png)

**Remark 3.4.** By employing the order conditions (2.5), we prove that the stability functions depend on $B^{-1}A$, and are independent of the individual matrices $A$ and $B$. We also present explicit matrix form of $B^{-1}A$ which plays an important role in the stability analysis of BIM. From the order conditions (2.5), it is easy to see that the order of BIM with block size $k$ is at least $k+1$. It has been proven that these methods converge at order $k+1$ when $k$ is odd and at order $k+2$ when $k$ is even [51,52].

In Theorem 3.3, we give a thorough analysis for the stability of BIM with $k$ up to 8. When $k = 9$, some roots of $|C_k(z)|$ have negative real part, which means that this method is not block $k^{th}$-step A-stable. Because the roots are computed numerically for $k > 8$, we do not have a mathematically provable stability theory.
3.2. Construction of BIM with $A$-stability. In this section, we explicitly construct some BIM with $A$-stability. From (3.4), (3.7) and (3.9), we obtain

$$
\begin{aligned}
\begin{cases}
A &= BN, \quad N = C_1 D_1 C_1^{-1} D_0^{-1}, \\
        \noalign{\hline}
        a &= -Ae = -BNe, \\
        \noalign{\hline}
        b &= A\bar{x} - Be = B\bar{x} - Be,
\end{cases}
\end{aligned}
$$

(3.17)

where $\bar{x} = (1, 2, \cdots, k)^T$, $N$ is given explicitly in (3.1). Hence, if $A$ (or $B$) is given, then $B$ (or $A$), $a$ and $b$ can also be fixed. The question is how to choose $A$ and $B$ such that the corresponding BIM has desirable properties? In the following, we focus on how to choose $A$ and $B$ in terms of the positive definiteness and sparsity.

**Definition 3.5.** A matrix $N$ is said to be positive stable if all its eigenvalues have positive real parts.

**Lemma 3.6.** ([39]) $N$ is positive stable if and only if there exists a symmetric positive definite (SPD) matrix $B$ such that

$$
BN + N^T B
$$

(3.18)

is positive definite.

Especially, if (3.18) is positive definite with a positive diagonal matrix $B$, $N$ is also called diagonally stable or “Lyapunov diagonally stable” [3, 25].

**Lemma 3.7.** ([3]) A matrix $N$ is diagonally stable if and only if for every nonzero positive semidefinite matrix $B$, $BN$ has a positive diagonal element.

Lemma 3.7 provides a necessary condition for a diagonally stable $N$ such that all the diagonal elements of $N$ are positive. From Theorem 3.2, the matrix $N$ for different $k$ ($2 \leq k \leq 8$) can be given explicitly as

$$
N_2 = \begin{pmatrix} 1 & 1/4 \\
-4 & 2 \end{pmatrix}, \quad N_3 = \begin{pmatrix} 1/2 & 1/2 & -1/18 \\
-2 & 1 & 2/9 \\
9/2 & -9/2 & 13/6 \end{pmatrix}, \quad N_4 = \begin{pmatrix} 1/6 & 3/4 & -1/6 & 1/48 \\
-4/3 & 1/2 & 4/9 & -1/24 \\
3/2 & -9/4 & 7/6 & 3/16 \\
-16/3 & 6 & -16/3 & 7/3 \end{pmatrix},
$$

$$
N_5 = \begin{pmatrix} -1/12 & 1 & -1/3 & 1/12 & -1/100 \\
-1 & 1/6 & 2/3 & -1/8 & 1/75 \\
-4/3 & 2 & -8/3 & 4/3 & 4/25 \\
25/4 & -25/3 & 25/3 & -25/4 & 149/60 \end{pmatrix},
$$

$$
N_6 = \begin{pmatrix} -17/60 & 5/4 & -5/9 & 5/24 & -1/20 & 1/180 \\
-4/5 & -1/12 & 8/9 & -1/4 & 4/75 & -1/180 \\
9/20 & -9/8 & 1/3 & 9/16 & -9/100 & 1/120 \\
-8/15 & 1 & -16/9 & 5/6 & 8/25 & -1/45 \\
5/4 & -25/12 & 25/9 & -25/8 & 89/60 & 5/36 \\
-36/5 & 45/4 & -40/3 & 45/4 & -36/5 & 157/60 \end{pmatrix},
$$

$$
N_7 = \begin{pmatrix} -9/20 & 3/2 & -5/6 & 5/12 & -3/20 & 1/30 & -1/294 \\
-2/3 & -17/60 & 10/9 & -5/12 & 2/15 & -1/36 & 2/735 \\
3/10 & -9/10 & 1/12 & 3/4 & -9/50 & 1/30 & -3/980 \\
5/12 & -5/6 & 25/18 & -25/12 & 59/60 & 5/18 & -5/294 \\
-6/5 & 9/4 & -10/3 & 15/4 & -18/5 & 97/60 & 6/49 \\
49/6 & -147/10 & 245/12 & -245/12 & 147/10 & -49/6 & 383/140 \end{pmatrix},
$$

13
When applied to PDEs, one needs to solve a large, strongly coupled linear system. Let the Runge-Kutta matrix $b\mathcal{A}$ be characterized by the Butcher tableau

\[
\begin{align*}
N_8 &= \begin{pmatrix}
-83/140 & 7/4 & -7/6 & 35/48 & -7/20 & 7/60 & -1/42 & 1/448 \\
-16/105 & 2/5 & -16/15 & 1/4 & 16/25 & -2/15 & 16/735 & -1/560 \\
7/6 & -49/20 & 49/12 & -245/48 & 49/10 & -49/12 & 243/140 & 7/64 \\
-64/7 & 56/3 & -448/15 & 35 & -448/15 & 56/3 & -64/7 & 199/70
\end{pmatrix},
\end{align*}
\]

respectively. For the above given $N$, we present three types of $B$ and $A$:

1. $B$ is chosen as a SPD matrix such that $A = BN$ is positive definite.

   From Lemma 3.6, we see that there exists a SPD matrix $B$ such that $BN$ is positive definite, but the matrix $B$ is difficult to find for a given $N$.

2. $B$ is chosen as a positive diagonal matrix such that $A = BN$ is positive definite.

   Generally speaking, there may not exist a positive diagonal matrix $B$ for a given $N$ such that $BN$ is positive definite. Lemma 3.7 provides a sufficient and necessary condition, there is no obvious way to explicitly find such a positive diagonal matrix. The theoretical characterization of the class of diagonally stable matrices is not computationally effective. Some optimization-based numerical algorithms were developed in [4, 20, 27, 33]. Below, we present some computed $B$ and $N$.

   Below we present some BIM with $A$-stability.

   **Algorithm 3.1 (BIM with $A$-stability)**

   Let $N$ be defined by $N_k$ for $2 \leq k \leq 8$, all methods defined by the following BIM matrices and vectors

   \[
   \begin{align*}
   B &= B_k, \quad A = BN_k, \quad a = -Ae, \quad b = A\bar{x} - Be, & \text{for} \ k = 2, 3, 4, \\
   B &= I, \quad A = BN_k, \quad a = -Ae, \quad b = A\bar{x} - Be, & \text{for} \ k = 5, 6, 7, 8,
   \end{align*}
   \]

   are $A$-stable.

4. **Comparisons with some fully implicit Runge-Kutta methods.** The $s$-stage IRK is an important class of time-integration schemes and has been studied extensively since they can offer high order accuracy and excellent stability [9, 50]. IRK can be characterized by the Butcher tableau

   \[
   \begin{array}{c|c}
   \bar{c} & \bar{A} \\
   \hline
   \bar{b}^T
   \end{array}
   \]

   where the Runge-Kutta matrix $\bar{A}$ is positive stable and dense, but not positive definite. When applied to PDEs, one needs to solve a large, strongly coupled linear

system at every time step. Because the lack of positive definiteness of $\hat{A}$, the linear system is often difficult to precondition and solve by iterative methods. On the other hand, for BIM the stability functions are independent of the matrices $A$ and $B$, so it is possible to construct different methods with the desired order and stability properties. Algorithms 3.1 provides schemes with up to $8^{th}$ order of accuracy. For these schemes, $B$ can be chosen as a positive diagonal matrix or an identity matrix, and $A$ is positive definite for $A$-stable algorithm with $2 \leq k \leq 4$.

Fig. 5: $\text{FIRK}$ ($\text{Gauss}(3)$ (top) and $\text{BIM}(k = 5, p = 6)$ (bottom), $(T_0 = t_0, T_1 = t_3, T_2 = t_6, T_3 = t_9, T_4 = t_{12}, T_5 = t_{15})$
In this section, we compare the $s$-stage FIRK algorithms (Gauss-Legendre and BIM) for solving the following ODE:

**Example 3.** \( y' = -250y + f(t), \quad t \in (0, 1], \quad y(0) = 0. \)

Here \( f(t) \) is chosen such that the exact solution is

\[
y(t) = \sum_{m=1}^{M} b_m \sin 2m \pi t,
\]

where \( b_m = \frac{9}{2m \pi} (\cos \frac{m \pi}{2} \cos m \pi) + \frac{5}{2m \pi} (\sin \frac{m \pi}{2} \cos m \pi) - \frac{7}{m \pi} \cos m \pi. \) Figure 4 shows that the smoothness of the solution becomes worse when \( M \) increases. In the experiments, we will use two different values of \( M = 50, 100. \)

Since the main computational costs for these two methods are the evaluations of the functions and solving the linear systems, we compare the errors and the order of convergence by setting the same number, denoted as \( N_f \), of function evaluations or the number of linear systems required to solve. In Tables 3-6, \( |y_e - y| \) denotes the maximum norm of the error between the exact solution \( y_e \) and the numerical solution \( y \) in the entire time interval. We see that none of the algorithms is able to achieve the optimal order if the time step size \( \tau \) is too large, the reason is that the solution is not smooth in part of the interval as shown in Figure 4. When the time step size \( \tau \) decreases, it is clear that all the algorithms converge at the optimal order. Table 3 show that the errors of BIM \((k = 2, p = 4)\) and BIM \((k = 3, p = 4)\) are smaller than Gauss(2). If we choose larger \( M = 100, \) the numerical results in Table 5 show

---

**Table 4:** The errors of $BIM(k = 4, p = 6)$, $BIM(k = 5, p = 6)$ and $FIRK(Gauss(3))$ for solving Example 3 with $M = 50$. $N_f$ is the number of function evaluations.

that BIM are almost the same as that of FIRK in terms of the errors. From the numerical results in Tables 4 and 6 we observe that the error of BIM($k = 5, p = 6$) is a little smaller than that of FIRK (Gauss(3)) algorithms when $M = 50$, and the errors are almost the same in the case $M = 100$. Tables 4 and 6 also show that Gauss(3) performs a little better than BIM($k = 4, p = 6$) in the case both $M = 50$ and $M = 100$.

In Figure 5, we compare a different aspect of FIRK (Gauss(3)) and BIM($k = 5, p = 6$). We observe that in a single time step Gauss(3) produces one solution at the cost of three function evaluations at three not equally spaced temporal locations, BIM($k = 5, p = 6$) produces five solutions at five equally spaced temporal locations. It is clear that FIRK and BIM have the same desirable properties of high order accuracy, good stability and requiring one starting value. However, $k$ in BIM is usually larger than $s$ in FIRK to achieve the same order of convergence. This means that a larger system needs to be solved for BIM at a time, although the number of blocks of BIM is fewer than FIRK at the final time; see Figure 5. Fortunately, the coefficient matrix of BIM is positive definite if the matrices $A$ and $B$ are properly chosen, and as a result, the systems are easier to solve. Moreover, BIM produces solutions at more temporal locations, that might be useful for certain applications.

5. BIM for parabolic PDEs. In this section, we study the proposed BIM for parabolic PDEs. We provide a convergence theory and some a priori error estimates for a model problem whose discretization consisting of BIM in time and the regular finite element in space. In order to solve the large systems resulting from the discretization, some parallel DD preconditioners are also introduced and studied.

5.1. A model problem and its finite element discretization. We consider a model parabolic equation

\[
\begin{align*}
\frac{\partial u}{\partial t} - \nabla \cdot (a(x) \nabla u) &= f, & \text{in } \Omega \times (0, T], \\
u(x, t) &= 0, & \text{on } \partial \Omega \times (0, T], \\
u(x, 0) &= u_0(x), & \text{in } \Omega,
\end{align*}
\]

(5.1)

where $\Omega \subset R^d$ ($d = 2$ or $3$) is a bounded, open polygonal (or polyhedra) domain, $0 < a_0 \leq a(x) < +\infty$ and $f(x, t) \in L^2(\Omega \times (0, T]), u_0(x) \in L^2(\Omega)$. For simplicity, we set $a(x) \equiv 1$ in some of the following discussions.

Let $0 = t_0 < t_1 < \cdots < t_m = T$ be a uniform temporal mesh and $\tau = t_i - t_{i-1}$. Suppose $u^i = u(x, t_i)$ is the solution at time $t_i$. Traditional time-stepping methods solve (5.1) time step by time step. We consider the method outlined in (2.12) for the
time discretization of (5.1) with block size \( k \leq m \) at time \( t_1, t_2, \cdots, t_k \), that is to find \( u^i \in H^1_0(\Omega) \), \( i = 1, 2, \cdots, k \), such that

\[
\begin{aligned}
    &\sum_{j=1}^{k} a_{1j}(u^j, v^1) + \tau \sum_{j=1}^{k} b_{1j}(\nabla u^j, \nabla v^1) = (g^1, v^1), \\
    &\sum_{j=1}^{k} a_{2j}(u^j, v^2) + \tau \sum_{j=1}^{k} b_{2j}(\nabla u^j, \nabla v^2) = (g^2, v^2), \\
    &\vdots \\
    &\sum_{j=1}^{k} a_{kj}(u^j, v^k) + \tau \sum_{j=1}^{k} b_{kj}(\nabla u^j, \nabla v^k) = (g^k, v^k),
\end{aligned}
\]

where

\[
(g^i, v^i) = -a_{i0}(u^0, v^i) + \tau b_{i0}(f^0, v^i) - \tau b_{i0}(\nabla u^0, \nabla v^i) + \tau \sum_{j=1}^{k} b_{ij}(f^j, v^i) \quad \forall v^i \in H^1_0(\Omega).
\]

Let \( u = (u^1, u^2, \cdots, u^k)^T \in (H^1_0(\Omega))^k \), \( f = (f^1, f^2, \cdots, f^k)^T \in (L^2(\Omega \times [0, T]))^k \). For any \( v \in (H^1_0(\Omega))^k \), the equivalent variational form of (5.2) is

\[
\begin{aligned}
    a_\tau(u, v) &\equiv (Au, v) + \tau (B\nabla u, \nabla v) = (g, v),
\end{aligned}
\]

where \( \nabla u = (\nabla u^1, \nabla u^2, \cdots, \nabla u^k)^T \) and

\[
(g, v) = \tau (Bf, v) - (a \otimes u^0, v) + \tau (b \otimes f^0, v) - \tau (b \otimes \nabla u^0, \nabla v).
\]

Next, we present the boundedness of the bilinear form \( a_\tau(\cdot, \cdot) \) defined in (5.3) from above and below under the \( \| \cdot \|_\tau \) norm for different matrices \( A \) and \( B \). The estimates are summarized in the following four lemmas.

**Lemma 5.1.** Suppose that \( B \) is SPD and \( A \) is positive definite, there exist positive constants \( C_0 \) and \( c_0 \) independent of \( \tau \) such that

\[
a_\tau(u, v) \leq C_0 \| u \|_\tau \| v \|_\tau \quad \forall u, v \in (H^1_0(\Omega))^k
\]

and

\[
a_\tau(u, u) \geq c_0 \| u \|^2_\tau \quad \forall u \in (H^1_0(\Omega))^k,
\]

where \( \| v \|^2_\tau = \| v \|^2 + \tau \| \nabla v \|^2 \).
Proof. It follows from the Cauchy-Schwarz inequality that
\[
a_{r}(u, v) = (Au, v) + \tau(B\nabla u, \nabla v)
\]
\[
= \sum_{i,j=1}^{k} a_{ij}(u^i, v^j) + \tau \sum_{i,j=1}^{k} b_{ij}(\nabla u^i, \nabla v^j)
\]
\[
\leq a_{\text{max}} \sum_{i,j=1}^{k} \|u^i\| \|v^j\| + \tau b_{\text{max}} \sum_{i,j=1}^{k} \|\nabla u^i\| \|\nabla v^j\|
\]
\[
\leq C_0(\|u\| \|v\| + \tau \|\nabla u\| \|\nabla v\|)
\]
\[
\leq C_0(\|u + \tau \|\nabla u\|\|v\| + \tau \|\nabla v\|) \frac{1}{2} \leq C_0 \|u\| \|v\|, \quad \forall u, v \in X
\]
(5.4)
where \(a_{\text{max}} = \max_{i,j=1}^{k} |a_{ij}|, b_{\text{max}} = \max_{i,j=1}^{k} |b_{ij}|\) and \(C_0 = k \max\{a_{\text{max}}, b_{\text{max}}\}\).

Further, since \(B\) is SPD and \(A\) is positive definite, we have
\[
a_{r}(u, u) = (Au, u) + \tau(B\nabla u, \nabla u)
\]
\[
\geq \frac{1}{2} \lambda_{\text{min}}(A + A^T) \|u\|^2 + \tau \lambda_{\text{min}}(B) \|\nabla u\|^2
\]
\[
\geq c_0 \|u\|^2, \quad \forall u, v \in (H^1_0(\Omega))^k
\]
(5.5)
where \(c_0 = \min\{\frac{1}{2} \lambda_{\text{min}}(A + A^T), \lambda_{\text{min}}(B)\}\).

Lemma 5.2. Suppose that \(B\) is SPD and \(A\) is not positive definite, we have
\[
a_{r}(u, v) \leq C_0 \|u\| \|v\|, \quad \forall u, v \in (H^1_0(\Omega))^k
\]
and
\[
a_{r}(u, u) \geq c_1 \|u\|^2 - c_2 \|u\|^2, \quad \forall u, v \in (H^1_0(\Omega))^k
\]
where \(C_0, c_1\) and \(c_2\) are positive constants and independent of \(\tau\).

Proof. The upper bound has been estimated in (5.4). Since \(B\) is SPD and \(A\) is not positive definite, the smallest eigenvalue of \(\frac{1}{2}(A + A^T)\) is negative, we have
\[
a_{r}(u, u) = (Au, u) + \tau(B\nabla u, \nabla u)
\]
\[
\geq \frac{1}{2} \lambda_{\text{min}}(A + A^T) \|u\|^2 + \tau \lambda_{\text{min}}(B) \|\nabla u\|^2
\]
\[
= c_1 \|u\|^2 - (c_2 + c_1) \|u\|^2, \quad \forall u, v \in (H^1_0(\Omega))^k
\]
(5.6)
where \(c_1 = \lambda_{\text{min}}(B)\) and \(c_2 = -\frac{1}{2} \lambda_{\text{min}}(A + A^T)\).

Lemma 5.3. Suppose that \(B\) is positive stable and \(A\) is an identity matrix, there exist positive constants \(C_0\) and \(c_3\) independent of \(\tau\) such that
\[
a_{r}(u, v) \leq C_0 \|u\| \|v\|, \quad \forall u, v \in V
\]
and
\[
\sup_{v \in V} \frac{a_r(u, v)}{\|v\|_\tau} \geq c_3 \|u\|_\tau, \quad \forall u \in V
\]
where \(V = (L^2(\Omega))^k + \tau(H^1_0(\Omega))^k\). Moreover, there exists \(u \in V\) such that \(a_r(u, v) \neq 0\) for any \(v \in V\).
Proof. See Lemma 3.1 and Lemma 3.3 in [40].

Let \( V_h \in (H_0^1(\Omega))^k \) be the piecewise linear continuous finite element space. The finite element solution of (5.3) is to find \( u_h \in V_h \) such that

\[
(5.7) \quad a_\tau(u_h, v_h) = (g, v_h) \quad \forall v_h \in V_h.
\]

**Theorem 5.4.** Suppose that \( B \) is SPD, there exists a positive constant \( C \) such that

\[
\| u - u_h \| \leq \frac{C h}{\sqrt{h^2 + \tau}} \| u - u_h \| \quad u_h \in V_h.
\]

Further, (1) if \( A \) is positive definite, (5.7) has a unique solution and

\[
\| u - u_h \| \leq C \| u \|, 
\]

(2) if \( A \) is not positive definite, but \( h^2/\tau \) is sufficiently small, (5.7) has a unique solution and

\[
\| u - u_h \| \leq C \| u \|, 
\]

where \( C > 0 \) is independent of \( h \) and \( \tau \).

Proof. From the a priori error estimate of the finite element method and the definition of the \( \tau \)-norm, we have

\[
\| u - u_h \|_2^2 \leq Ch^2 \| u - u_h \|_1 \leq \frac{Ch^2}{\tau} \| u - u_h \|_\tau^2 - \frac{Ch^2}{\tau} \| u - u_h \|_\tau^2,
\]

which implies

\[
(5.8) \quad \| u - u_h \| \leq \frac{Ch}{\sqrt{h^2 + \tau}} \| u - u_h \|_\tau.
\]

If \( A \) is positive definite, it follows from (5.4) and (5.5) that

\[
a_\tau(u - u_h, u) \leq C \| u - u_h \| \| u \|_\tau,
\]

and

\[
a_\tau(u - u_h, u) = a_\tau(u - u_h, u - u_h) \geq c_0 \| u - u_h \|_\tau^2.
\]

It is obvious that \( \| u - u \|_\tau \leq C \| u_h \|_\tau \).

If \( A \) is not positive definite, it follows from (5.6) and (5.8) that

\[
a_\tau(u - u_h, u) = a_\tau(u - u_h, u - u_h) \geq c_1 \| u - u_h \|_\tau^2 - (c_1 + c_2) \| u - u_h \|_\tau^2
\]

\[
\geq c_1 \left( c_1 - \frac{Ch^2}{\tau + h^2} \right) \| u - u_h \|_\tau^2.
\]

Suppose \( h^2/\tau \) is sufficiently small, we have \( \| u - u_h \|_\tau \leq C \| u \|_\tau \), where \( C > 0 \) is independent of \( h \) and \( \tau \).
Discretized by the finite element basis functions \( \phi_j \) \((1 \leq j \leq N)\), the bilinear form (5.7) is equivalent to the following linear system of algebraic equations

\[
\mathbf{A} \mathbf{U} \equiv (\mathbf{A} \otimes \mathbf{M} + \tau \mathbf{B} \otimes \mathbf{K}) \mathbf{U} = \mathbf{F}, \quad \mathbf{A} \in \mathbb{R}^{kN \times kN}, \quad \mathbf{F} \in \mathbb{R}^{kN},
\]

where \( \mathbf{A} \in \mathbb{R}^{k \times k} \) and \( \mathbf{B} \in \mathbb{R}^{k \times k} \) are the BIM matrices, \( \mathbf{M} \in \mathbb{R}^{N \times N} \) and \( \mathbf{K} \in \mathbb{R}^{N \times N} \) denote the mass matrix and the stiffness matrix, respectively. \( \mathbf{U} \) and \( \mathbf{F} \) are vectors corresponding to the nodal values of \( \mathbf{u}_h \) and \( \mathbf{g} \).

When BIM is used for PDEs, it results in a \( kN \times kN \) linear system (5.9). In practice, \( N \) is usually large and \( \mathbf{K} \) is highly ill-conditioned, a preconditioner is important if the system is solved by a Krylov subspace method.

### 5.2. Parallel preconditioning techniques

Note that (5.9) also arises from the classical implicit Runge-Kutta methods, in such a situation \( \mathbf{A} \) is an identity matrix and \( \mathbf{B} \) is the Runge-Kutta matrix which is dense, non-symmetric and not positive definite. Depending on how \( \mathbf{B} \) is approximated, several preconditioners are available [28–30, 35, 40, 43, 47]. Different from the Runge-Kutta algorithms, for BIM, the matrix \( \mathbf{B} \) in (5.9) is a positive diagonal matrix or an identity matrix, the matrix \( \mathbf{A} \) is dense and positive definite or positive stable. Now we present some preconditioners for BIM based on the partition of the matrices \( \mathbf{M} \) and \( \mathbf{K} \) using an overlapping decomposition of the spatial mesh [46,49].

Let \( \mathcal{T}_H \) be a coarse mesh covering \( \Omega \) with mesh size \( H \), and \( \mathcal{T}_h \) be a fine mesh with mesh size \( h \). Denote \( \mathcal{T}_0 \) and \( \mathcal{T}_h \) as the finite element spaces consisting of continuous piecewise linear functions associated with the meshes \( \mathcal{T}_H \) and \( \mathcal{T}_h \), respectively. We introduce a non-overlapping decomposition \( \Omega = \bigcup_{i=1}^{N_p} \Omega_i \) on \( \mathcal{T}_h \), where each \( \Omega_i \) is a union of some elements from \( \mathcal{T}_h \), and \( N_p \) is the number of subdomains. Then, the overlapping subdomains \( \Omega_i' \) can be obtained by adding some layers of fine mesh elements from the adjacent subdomains. Denote the finite element subspace on \( \Omega_i' \) as \( \mathcal{V}_i = \mathcal{V}_h \cap H_0^1(\Omega_i') \) and let \( N_i \) be the dimension of \( \mathcal{V}_i \), we obtain

\[
\mathcal{V}_h = (\mathcal{V}_h)^k \quad \text{and} \quad \mathcal{V}_i = (\mathcal{V}_i)^k, \quad (i = 0, 1, 2, \ldots, N_p),
\]

where \( k \) is the block size of the chosen BIM. Define the single time step restriction matrix \( \mathcal{R}_i \in \mathbb{R}^{N_i \times N} : \mathcal{V}_h \rightarrow \mathcal{V}_i \), the block restriction matrix \( \mathcal{R}_i \in \mathbb{R}^{kN_i \times kN} : \mathcal{V}_h \rightarrow \mathcal{V}_i \) can then be defined as

\[
\mathcal{R}_i = \text{diag}\{\mathcal{R}_i, \mathcal{R}_i, \ldots, \mathcal{R}_i\}.
\]

Therefore, the space \( \mathcal{V}_h \) admits the following decomposition

\[
\mathcal{V}_h = \sum_{i=1}^{N_p} \mathcal{R}_i^T \mathcal{V}_i \quad \text{and} \quad \mathcal{V}_h = \mathcal{R}_0^T \mathcal{V}_0 + \sum_{i=1}^{N_p} \mathcal{R}_i^T \mathcal{V}_i,
\]

which are needed for the one-level and two-level methods, respectively. Here \( \mathcal{R}_i^T \) denotes the transpose of \( \mathcal{R}_i \) \((i = 0, 1, \ldots, N_p)\). For \( \mathcal{R}_0 \) there are many choices, in this paper, we only consider these based on the basis functions of the coarse and fine finite element spaces. \( \mathcal{R}_i \) \((i > 0)\) is a sub-identity matrix whose diagonal elements corresponding to the subdomain \( \Omega_i \) are one and all other elements are zero. Note that the coarse and fine meshes don’t have to be nested. Then, we can define the following preconditioners.
Table 7: The condition numbers of the matrices with preconditioners \( \mathcal{P}^{(1)} \) and \( \mathcal{P}^{(2)} \) for Algorithm 3.1 applied to Example 4

- One-level additive Schwarz preconditioner

\[
\mathcal{P}^{(1)} = \sum_{i=1}^{N_p} \mathcal{R}_i^T A_i^{-1} \mathcal{R}_i.
\]

- Two-level additive Schwarz preconditioner

\[
\mathcal{P}^{(2)} = \mathcal{R}_0^T A_0^{-1} \mathcal{R}_0 + \sum_{i=1}^{N_p} \mathcal{R}_i^T A_i^{-1} \mathcal{R}_i.
\]

where \( A_0 = \mathcal{R}_0 A \mathcal{R}_0^T \) is the restriction of \( A \) to the coarse space \( V_0 \), \( A_i = \mathcal{R}_i A \mathcal{R}_i^T = A \otimes M_i + \tau B \otimes K_i \) is the restriction of \( A \) to the subspaces \( V_i \) \((i \geq 1)\), and the matrices \( M_i \) and \( K_i \) are defined by

\[
M_i = \mathcal{R}_i M \mathcal{R}_i^T \quad \text{and} \quad K_i = \mathcal{R}_i K \mathcal{R}_i^T.
\]

All inverses in (5.11) and (5.12) are understood as subspace inverse. In practical applications, they are often approximated to save computational cost.

Remark 5.5. We remark that it is important to select the appropriate preconditioner for each practical application. For example if the number of spatial variables is small, such as in ODEs, then the DD method is not necessary. The one-level DD method is useful when the number of processors is small, and the two-level DD methods are for the situations when the number of subdomains is large.

5.3. Some numerical studies of the preconditioners. In this section, we investigate the performance of the proposed Schwarz preconditioners in terms of the condition number, the eigenvalue distribution and the number of GMRES iterations. In the experiments, \( \Omega = [0, 1] \times [0, 1] \) is covered by a uniform coarse mesh of size \( H = 1/16 \), and a uniform fine mesh of size \( h = 1/64 \). The spatial fine mesh is decomposed into \( 4 \times 4 \) subdomains. The overlapping size is 1 and the time step size \( \tau \) is chosen as \( \tau = h^{2/p} \) \((p = k + 1 \text{ when } k \text{ is odd and } p = k + 2 \text{ when } k \text{ is even})\), where \( p \) denotes the order of accuracy in time. All the preconditioners are constructed exactly; i.e., the inverse of the submatrix and coarse matrix are computed exactly.

**Example 4.** We consider an advection-diffusion equation

\[
\begin{cases}
    u_t - \Delta u + u_x + u_y = f, & \text{in } \Omega \times (0, T], \\
    u(x, y, t) = 0, & \text{on } \partial \Omega \times (0, T], \\
    u(x, y, 0) = \sin(\pi x) \sin(\pi y), & \text{in } \Omega,
\end{cases}
\]
Fig. 6: All eigenvalues of the matrices $\mathcal{A}$ (blue) and $\mathcal{P}^{(2)}\mathcal{A}$ (red) for Algorithm 3.1, zoom-in is for the eigenvalues of $\mathcal{A}$ (near 0)

where $f$ is chosen such that the exact solution is $u(x, y, t) = \sin(\pi x) \sin(\pi y) e^{-t}$.

We study Algorithm 3.1 for Example 4. Table 7 presents the 2-norm condition number of the matrix $\mathcal{A}$ and of $\mathcal{A}$ preconditioned by $\mathcal{P}^{(1)}$ and $\mathcal{P}^{(2)}$, respectively. It shows that the condition number of $\mathcal{A}$ grows firstly with $k$ from 2 to 4, and then there is a drop from $k = 4$ to $k = 5$, afterward, it increases again with $k$ ranging from 5 to 8. The reason is that the BIM matrix $\mathcal{B}$ is chosen as a positive diagonal

matrix for the cases $k = 2, 3, 4$ and as an identity matrix for the cases $k = 5, 6, 7, 8$. It seems that the preconditioner with identity matrix $B$ yields a lower condition number than the preconditioner with the positive diagonal matrix $B$. All the preconditioners are able to reduce the condition number, which increases with $k$, and the two-level preconditioner $P^{(2)}$ performs better than the one-level preconditioner $P^{(1)}$.

When the Schwarz preconditioners are accelerated by GMRES [46, 49], the eigenvalue distribution of the preconditioned matrix is an important indicator for the performance of GMRES. In Figure 6, we plot the eigenvalues of $A$ and the preconditioned matrix $P^{(2)}A$ for Algorithms 3.1. It is clear that some eigenvalues of $A$ are close to the origin and the eigenvalues of $P^{(2)}A$ are all away from the origin. Moreover, it is interesting that the eigenvalues of $A$ are clustered on a single line for BIM with a positive diagonal matrix $B$ and are clustered on $k$ lines for BIM with an identity matrix $B$.

Finally, we solve Example 4 using GMRES preconditioned by $P^{(1)}$ and $P^{(2)}$. In the implementation, GMRES(30) is used with relative tolerance $10^{-6}$. In Table 8, we report iteration counts for $P^{(1)}$ by varying the number of subdomains $N_p$, overlapping size $\delta$ and block size $k$, the spatial mesh size and time step size are $h = 1/128$ and $\tau = h^{2/p}$, respectively. For a given block size $k$, it shows the iteration counts decrease
with the increase of the overlapping size, and grow with the number of subdomains. Moreover, the iteration counts increase a little from $k = 2$ to $k = 4$, and changes slightly from $k = 4$ to $k = 8$. For the two-level preconditioner $\mathbf{P}^{(2)}$, the coarse and fine mesh sizes are $H = 1/16$ and $h = 1/128$, respectively. The results in Table 9 show that the iteration counts decrease with the overlapping size and is bounded independently of the number of subdomains. Further, the number of iterations doesn’t change much with the block size $k$.

6. Conclusions. In this paper we developed a unified framework for the class of BIM with $A$-stability for parabolic problems. Similar to IRK, BIM offers high order of accuracy, desirable stability properties, and requires a single initial value. Because of the flexibility in selecting the BIM matrices, the resulting large, highly ill-conditioned linear system is easier to precondition and solve than that from IRK. For some block sizes, we derived the matrix form of $B^{-1}A$ explicitly, and show that it is positive stable, moreover, we also derived positive diagonal matrices $B$ and positive definite matrices $A$ explicitly. The other important result is that, the positive definiteness of the coupled matrix $A$ depends only on the positive definiteness of the spatial matrix $K$. Using the properties of the BIM matrices, we developed a finite element theory which is not possible for IRK because the lack of the positive definiteness of the Runge-Kutta matrix. We also introduced and studied numerically some DD preconditioners that are quite effective for the system of equations arising from the BIM discretization.
